1 Introduction

This report presents and discusses a collection of programs written in the Declarative Ada programming language [8]. It is intended as supplementary reading to [7] and [8].

The programs are grouped as follows:

1. Five sorting programs that use lists, trees, and recursion.
2. Two programs that use arrays and parallel loops.
3. Two programs that involve networks of processes that communicate using streams.
4. A larger program, dining philosophers, that includes nondeterminism.

Although related programs are grouped together, this report is not intended to be a systematic presentation of Declarative Ada features or programming paradigms. Nor is it intended to be a tutorial. The goals and methods of parallel programming with Declarative Ada are described in [7], which also discusses some of the examples in this report. Additionally, [3] and [4] describe parallel programming techniques with single-assignment variables.

In some cases, the programs could be more elegantly written if Declarative Ada was based on a larger subset of Ada [1]. For instance, enumeration types, unconstrained array types, variant record types, case statements, packages, and generic units would be useful. However, the overall structure of the programs and the methods of expressing parallelism would remain the same.

All of the programs presented are complete and have been compiled and executed using an implementation of Declarative Ada developed by the author [6]. A test program and actual test output is given for each program. Correct execution with a particular set of test data is no guarantee of a correct program. However, in practice methodical testing is an important part of program development.

The programs presented do not constitute a test suite for an implementation of Declarative Ada. An actual test suite is discussed in [6].

2 Lists, Trees, and Recursion

Dynamically allocated data structures such as lists and trees provide a means of communication and synchronization between parallel processes. The production and consumption of dynamic data structures can be executed in parallel. Synchronization occurs automatically: consumer processes suspend when they require an element that is undefined, and resume execution after the element is defined by the producer process. For instance, one process (the consumer) can be searching a list as it is being created by another process (the producer). Parallelism of this kind is often called pipeline parallelism.

Recursion is the method of creating and traversing dynamically allocated data structures.

In this section we present five different list sorting programs: insertion sort, mergesort, quicksort, treesort, and heapsort. The first three use only lists. The latter two use trees as intermediate data structures.

It is notable that, with the addition of appropriate packaging, each of the programs is a correct sequential Ada program to sort a list. The results of the programs are entirely independent of whether the execution is parallel or sequential.

2.1 Sorting Problem Specification

A function is required that satisfies the following specification:

```
type node;
type list   is access node;
type node is record
                head : integer;
                tail   : list;
             end record;

function sort(unsorted : list) return list;
-- Input Condition:
--    unsorted is finite and acyclic.
-- Output Condition:
--    sort(unsorted) is a permutation of unsorted, and
--    sort(unsorted) is in ascending order.
```

2.2 Insertion Sort

2.2.1 The Program

```
type node;
type list   is access node;
type node is record
                head : integer;
                tail   : list;
             end record;

function insert(item : integer; items : list) return list is
begin
    if items = null then
        return new node'(item, null);
    else
        if item <= items.head then
            return new node'(item, items);
        else
            return new node'(items.head, insert(item, items.tail));
        end if;
    end if;
end insert;
```

```
function sort(unsorted : list) return list is
begin
    if unsorted = null then
        return null;
    else
        return insert(unsorted.head, sort(unsorted.tail));
    end if;
end sort;
```

2.2.2 Discussion

The insertion sort program demonstrates parallel execution derived from functional composition.

If the unsorted list is the empty list, the sort function returns the empty list (which is trivially in ascending order). Otherwise, the sort function returns the head of the unsorted list inserted into its correct position in the recursively sorted tail of the unsorted list. The recursion terminates (if the unsorted list is finite and acyclic), because each recursive call sorts a list with one fewer elements.

At each level of a sort call, the insert and recursive sort processes are executed in parallel. Therefore, the complete executing program consists of a pipeline of parallel sort and insert processes.

2.3 Mergesort

2.3.1 The Program

```
type node;
type list   is access node;
type node is record
                head : integer;
                tail   : list;
            end record;
```

```
procedure split(items : in list; left, right : out list) is
    left_tail, right_tail : list;
begin
    if items = null or else items.tail = null then
        left  := items;
        right := null;
    else
        split(in items.tail.tail, out left_tail, out right_tail);
        left  := new node'(items.head, left_tail);
        right := new node'(items.tail.head, right_tail);
    end if;
end split;

function merge(left, right : list) return list is
begin
    if left = null then
        return right;
    elsif right = null then
        return left;
    elsif left.head <= right.head then
        return new node'(left.head, merge(left.tail, right));
    else
        return new node'(right.head, merge(left, right.tail));
    end if;
end merge;

function sort(unsorted : list) return list is
    left, right : list;
begin
    if unsorted = null or else unsorted.tail = null then
        return unsorted;
    else
        split(in unsorted, out left, out right);
        return merge(sort(left), sort(right));
    end if;
end sort;
```

2.3.2 Discussion

The mergesort program demonstrates parallel execution derived from both functional composition and parallel composition of statements. Use of functional composition alone can be unwieldy or inefficient when functions have multiple outputs, function calls are nested deeply, or the same function call

occurs in many places.

If the unsorted list is the empty list or a list with one element, the sort function returns the unsorted list (which is trivially in ascending order). Otherwise, the unsorted list is split into left and right sublists that together form a permutation of the unsorted list and differ in length by at most one element. The sort function returns the ordered merge of the recursively sorted left and right sublists.

Since the unsorted list has at least two elements, each sublist has at least one element and (if the unsorted list is finite and acyclic) has at least one fewer elements than the unsorted list. Therefore, the recursion terminates (if the unsorted list is finite and acyclic), because each recursive call sorts a list with fewer elements.

At each level of a sort call, the split, merge, and the two recursive sort processes are executed in parallel. In particular, the two recursive sort processes are independent of each other and are executed in parallel without interaction. Therefore, the complete executing program consists of a network of parallel sort, split, and merge processes.

2.4 Quicksort

2.4.1 The Program

```
type node;
type list  is access node;
type node is record
                head : integer;
                tail  : list;
             end record;
```

```
procedure partition(pivot       : in  integer;
                    items       : in  list;
                    left, right : out list      ) is
    left_tail, right_tail : list;
begin
    if items = null then
        left := null;
        right := null;
    else
        if items.head <= pivot then
            partition(in pivot, in items.tail, out left_tail, out right);
            left := new node'(items.head, left_tail);
        else
            partition(in pivot, in items.tail, out left, out right_tail);
            right := new node'(items.head, right_tail);
        end if;
    end if;
end partition;

function quicksort(unsorted, tail : list) return list is
    left, right : list;
begin
    if unsorted = null then
        return tail;
    else
        partition(in unsorted.head, in unsorted.tail, out left, out right);
        return quicksort(left, new node'(unsorted.head, quicksort(right, tail)));
    end if;
end quicksort;

function sort(unsorted : list) return list is
begin
    return quicksort(unsorted, null);
end sort;
```

2.4.2 Discussion

The quicksort program demonstrates parallel execution derived from both functional composition and parallel composition of statements.

The quicksort function returns a list consisting of the elements of the unsorted list in ascending order, followed by the tail list. The sort function calls the quicksort function with the empty list as the tail list.

If the unsorted list is the empty list, the quicksort function returns the tail list (trivially meeting the specification). Otherwise, the tail of the unsorted list is partitioned into left and right sublists. The left sublist is all elements less than or equal to the head of the unsorted list, and the right sublist is all elements greater than the head of the unsorted list. The quicksort function returns the concatenation of the recursively sorted left sublist, the head of the unsorted list, the recursively sorted right sublist, and the tail list. The tail parameter of the quicksort function provides a method of concatenation.

Since the left and right lists are sublists of the tail of the unsorted list, (if the unsorted list is finite and acyclic) they each have at least one fewer element than the unsorted list. Therefore, the recursion terminates (if the unsorted list is finite and acyclic), because each recursive call sorts a list with fewer elements.

At each level of a sort call, the partition and the two recursive quicksort processes are executed in parallel. In particular, the two recursive quicksort processes are independent of each other and are executed in parallel without interaction. Therefore, the complete executing program consists of a network of parallel quicksort and partition processes.

2.5 Treesort

2.5.1 The Program

```
type node;
type list   is access node;
type node is record
                head : integer;
                tail   : list;
             end record;

type tree_node;
type tree       is access tree_node;
type tree_node is record
                     left   : tree;
                     value : integer;
                     right  : tree;
                  end record;
```

```
function insert(item : integer; t : tree) return tree is
begin
    if t = null then
        return new tree_node'(null, item, null);
    elsif item < t.value then
        return new tree_node'(insert(item, t.left), t.value, t.right);
    else
        return new tree_node'(t.left, t.value, insert(item, t.right));
    end if;
end insert;

function build(items : list) return tree is
begin
    if items = null then
        return null;
    else
        return insert(items.head, build(items.tail));
    end if;
end build;

function traverse(t : tree; tail : list) return list is
begin
    if t = null then
        return tail;
    else
        return traverse(t.left, new node'(t.value, traverse(t.right, tail)));
    end if;
end traverse;

function sort(unsorted : list) return list is
begin
    return traverse(build(unsorted), null);
end sort;
```

2.5.2 Discussion

The treesort program demonstrates parallel execution derived from functional composition, operating on tree data structures.

Sort: The sort function returns the in-order traversal of an ordered tree built from the unsorted list. The tree is built such that it has the same elements as the unsorted list, and all the elements to the left of each node

are less than the node, and all the elements to the right of each node are greater than or equal to the node.

The build and traverse processes are executed in parallel. However, the dependence of the traverse process on the result of the build process means that their execution can be overlapped only to a small degree.

Build: If the items list is the empty list, the build function returns the empty tree (which is trivially ordered). Otherwise, the build function returns the head of the items list inserted into its correct position in the tree recursively built from the tail of the items list. The recursion terminates and builds a finite and acyclic tree (if the items list is finite and acyclic), because each recursive call builds a tree from a list with one fewer elements.

At each level of a build call, the insert and recursive build processes are executed in parallel. Therefore, a complete executing build call consists of a pipeline of parallel build and insert processes. More overlapping of execution can be obtained in building an ordered tree than in building an ordered list, because insertions on different branches of the tree are independent of each other.

Traverse: If the tree is the empty tree, the traverse function returns the tail list. Otherwise, the traverse function returns the concatenation of the recursively traversed left side of the tree, the root node of the tree, the recursively traversed right side of the tree, and the tail list. The tail parameter of the traverse function (which is the empty list in the outermost call) provides a method of concatenation. The recursion terminates (if the tree is finite and acyclic), because each recursive call traverses a tree with fewer elements.

At each level of a traverse call, the two recursive traverse processes are independent of each other and are executed in parallel without interaction. Therefore, a complete executing traverse call consists of a tree of parallel traverse processes.

2.6 Heapsort

2.6.1 The Program

```
type node;
type list   is access node;
type node is record
                head : integer;
                tail   : list;
             end record;

type heap_node;
type heap       is access heap_node;
type heap_node is record
                      left       : heap;
                      left_size  : integer;
                      value      : integer;
                      right      : heap;
                      right_size : integer;
                   end record;

function insert(item : integer; h : heap) return heap is
begin
   if h = null then
      return new heap_node'(null, 0, item, null, 0);
   elsif item < h.value then
      if h.left_size < h.right_size then
         return new heap_node'(insert(h.value, h.left), h.left_size + 1,
                               item, h.right, h.right_size);
      else
         return new heap_node'(h.left, h.left_size, item,
                               insert(h.value, h.right), h.right_size + 1);
      end if;
   else
      if h.left_size < h.right_size then
         return new heap_node'(insert(item, h.left), h.left_size + 1,
                               h.value, h.right, h.right_size);
      else
         return new heap_node'(h.left, h.left_size, h.value,
                               insert(item, h.right), h.right_size + 1);
      end if;
   end if;
end insert;
```

```
function delete_root(h : heap) return heap is
begin
    if h.left = null then
        return h.right;
    elsif h.right = null then
        return h.left;
    elsif h.left.value < h.right.value then
        return new heap_node'(delete_root(h.left), h.left_size − 1,
                              h.left.value, h.right, h.right_size);
    else
        return new heap_node'(h.left, h.left_size, h.right.value,
                              delete_root(h.right), h.right_size − 1);
    end if;
end delete_root;

function build(items : list) return heap is
begin
    if items = null then
        return null;
    else
        return insert(items.head, build(items.tail));
    end if;
end build;

function dismantle(h : heap) return list is
begin
    if h = null then
        return null;
    else
        return new node'(h.value, dismantle(delete_root(h)));
    end if;
end dismantle;

function sort(unsorted : list) return list is
begin
    return dismantle(build(unsorted));
end sort;
```

2.6.2 Discussion

The heapsort program demonstrates parallel execution derived from functional composition, operating on tree data structures.

Sort: The sort function returns a list created by dismantling an ordered and balanced heap built from the unsorted list. The heap is built such that it has the same elements as the unsorted list, all the elements beneath each node are greater than or equal to the node (ordering), and the number of elements to the left and right of each node differ by at most one (balancing).

The dismantle and build processes are executed in parallel. However, the dependence of the dismantle process on the result of the build process means that their execution can be overlapped only to a small degree.

Build: If the items list is the empty list, the build function returns the empty heap (which is trivially ordered and balanced). Otherwise, the build function returns the head of the items list inserted into its correct position in the heap recursively built from the tail of the items list. The recursion terminates and builds a finite and acyclic heap (if the items list is finite and acyclic), because each recursive call builds a heap from a list with one fewer elements.

At each level of a build call, the insert and recursive build processes are executed in parallel. Therefore, a complete executing build call consists of a pipeline of parallel build and insert processes. More overlapping of execution can be obtained in building an ordered heap than in building an ordered list, because insertions on different branches of the heap are independent of each other.

Dismantle: If the heap is the empty heap, the dismantle function returns the empty list. Otherwise, the dismantle function returns a list with as its head the root (minimum) element of the heap, and as its tail the dismantling of the heap formed by deleting the root node (retaining ordering but not necessarily balancing). The recursion terminates (if the heap is finite and acyclic), because each recursive call dismantles a heap with one fewer elements.

At each level of a dismantle call, the delete_root and recursive dismantle processes are executed in parallel. Therefore, a complete executing dismantle call consists of a pipeline of parallel dismantle and delete_root processes. In many cases, processes will operate on different branches of the heap and be independent.

2.7 A Test Program

The following test program provides a general set of tests applicable to any sorting program.

```
function build_list(size, i1, i2, i3, i4, i5 : in integer) return list is
begin
    if size = 0 then
        return null;
    else
        return new node'(i1, build_list(size − 1, i2, i3, i4, i5, 0));
    end if;
end build_list;

procedure put_items(items : in list) is
begin
    sequential
    put(items.head);
    if items.tail /= null then
        sequential
        put(" ");
        put_items(items.tail);
    end if;
end put_items;

procedure put_list(items : in list) is
begin
    if items = null then
        put("empty");
    else
        put_items(items);
    end if;
end put_list;
```

```
function equal_lists(list_1, list_2 : list) return Boolean is
begin
    if list_1 = null and list_2 = null then
        return true;
    elsif (list_1 = null and list_2 /= null) or
          (list_2 = null and list_1 /= null) then
        return false;
    else
        return list_1.head = list_2.head and then
                equal_lists(list_1.tail, list_2.tail);
    end if;
end equal_lists;

procedure test(message : in string; unsorted, expected : in list) is
    sorted : list;
begin
    sequential
    put(message); new_line;
    put("      Unsorted list: "); put_list(unsorted); new_line;
    sorted := sort(unsorted);
    put("      Sorted list:   "); put_list(sorted); new_line;
    if equal_lists(sorted, expected) then
        put("Succeeded");
    else
        put(">>>> FAILED <<<<");
    end if;
    new_line; new_line;
end test;
```

```
procedure main is
    x : integer;
begin
    sequential
    put("Testing Sorting"); new_line;
    put("———————————"); new_line;
    new_line;
    x := 0;
    test("Empty list:",
        build_list(0, x, x, x, x, x), build_list(0, x, x, x, x, x));
    test("Single item:",
        build_list(1, 1, x, x, x, x), build_list(1, 1, x, x, x, x));
    test("Pair in ascending order:",
        build_list(2, 1, 2, x, x, x), build_list(2, 1, 2, x, x, x));
    test("Pair in descending order:",
        build_list(2, 2, 1, x, x, x), build_list(2, 1, 2, x, x, x));
    test("Pair with same values:",
        build_list(2, 1, 1, x, x, x), build_list(2, 1, 1, x, x, x));
    test("List in ascending order:",
        build_list(5, 1, 2, 2, 3, 4), build_list(5, 1, 2, 2, 3, 4));
    test("List in descending order:",
        build_list(5, 4, 3, 2, 2, 1), build_list(5, 1, 2, 2, 3, 4));
    test("List with same values:",
        build_list(5, 1, 1, 1, 1, 1), build_list(5, 1, 1, 1, 1, 1));
    test("List in random order:",
        build_list(5, 3, 1, 2, 4, 2), build_list(5, 1, 2, 2, 3, 4));
    put("FINISHED."); new_line;
end main;
```

2.8 Test Output

```
Testing Sorting
---------------

Empty list:
    Unsorted list: empty
    Sorted list:   empty
Succeeded

Single item:
    Unsorted list: 1
    Sorted list:   1
Succeeded
```

```
Pair in ascending order:
    Unsorted list: 1 2
    Sorted list:   1 2
Succeeded

Pair in descending order:
    Unsorted list: 2 1
    Sorted list:   1 2
Succeeded

Pair with same values:
    Unsorted list: 1 1
    Sorted list:   1 1
Succeeded

List in ascending order:
    Unsorted list: 1 2 2 3 4
    Sorted list:   1 2 2 3 4
Succeeded

List in descending order:
    Unsorted list: 4 3 2 2 1
    Sorted list:   1 2 2 3 4
Succeeded

List with same values:
    Unsorted list: 1 1 1 1 1
    Sorted list:   1 1 1 1 1
Succeeded

List in random order:
    Unsorted list: 3 1 2 4 2
    Sorted list:   1 2 2 3 4
Succeeded

FINISHED.
```

3 Arrays and Loops

Loops provide a convenient method of defining and accessing the components of array data structures. (In fact, because of the single-assignment restriction, the only sensible use of loops is array manipulation.) Parallel

loops can be used to define the components of arrays in parallel. Where data dependencies exist, synchronization occurs automatically through processes suspending when they access undefined components.

In this section we present two programs that use arrays and loops: the all-points shortest-path problem and Dirichlet's problem (a simple grid problem). As with the sorting programs in the previous section, with appropriate packaging, both programs are correct sequential Ada programs.

For simplicity, the sizes of arrays are defined by constants. In practice, oversized arrays could be declared and only partially used. (A larger subset of Ada could include unconstrained array types and dynamically sized arrays.)

3.1 The All-Points Shortest-Path Problem

3.1.1 Problem Specification

A function is required that satisfies the following specification:

```
type path_lengths is array(1 .. N, 1 .. N) of integer;

function shortest_paths(edges : path_lengths) return path_lengths;
-- Input Condition:
--    N ≥ 1, and
--    for some weighted directed graph G, with vertices V1 .. VN:
--        ∀ i ∈ 1..N, j ∈ 1..N : edges(i, j) = weight of edge from Vi to Vj, and
--    G has no cycles of negative length, and
--    ∀ i ∈ 1..N : edges(i, i) = 0.
-- Output Condition:
--    ∀ i ∈ 1..N, j ∈ 1..N :
--        shortest_paths(edges)(i, j) = length of shortest path from Vi to Vj.
```

3.1.2 The Program

```
N : constant integer := 4;

type path_lengths     is array(1 .. N, 1 .. N) of integer;
type all_path_lengths is array(0 .. N) of path_lengths;

function min(x, y : integer) return integer is
begin
    if x < y then return x; else return y; end if;
end min;

function shortest_paths(edges : path_lengths) return path_lengths is
    paths : all_path_lengths;
begin
    paths(0) := edges;
    for k in 1 .. N loop
        for i in 1 .. N loop
            for j in 1 .. N loop
                paths(k)(i, j) := min(paths(k - 1)(i, j),
                                      paths(k - 1)(i, k) + paths(k - 1)(k, j));
            end loop;
        end loop;
    end loop;
    return paths(N);
end shortest_paths;
```

3.1.3 Discussion

The program to solve the all-points shortest-path problem demonstrates parallel execution derived from parallel loops.

The shortest_paths function defines the paths array to be intermediate results satisfying the following specification:

$$\forall\ k \in 0..N,\ i \in 1..N,\ j \in 1..N :$$
$$\text{paths}(k)(i, j) = \text{length of shortest path from } V_i \text{ to } V_j \text{ with intermediate vertices only in } V_1..V_k.$$

The paths array and the result of the shortest_paths function are defined as follows:

- paths(0) = edges.

This is correct because edges(i, j) is the shortest path from V_i to V_j with no intermediate vertices.

- $\forall$ k $\in$ 1..N, i $\in$ 1..N, j $\in$ 1..N :
  paths(k)(i, j) = min(paths(k−1)(i, j),
  paths(k−1)(i, k) + paths(k−1)(k, j)).
  This is correct by induction on k.

- The shortest_paths function returns paths(N).
  This is correct because paths(N)(i, j) is the shortest path from V_i to V_j with no restriction on intermediate vertices.

The N iterations of each loop statement are executed in parallel. Therefore, the executing program consists of N^3 parallel assignment statement processes, each defining the value of a different paths(k)(i, j). However, the dependence of the value of paths(k)(i, j) on the values of paths(k−1)(i, j), paths(k−1)(i, k), and paths(k−1)(k, j) restricts the order and overlapping of the execution of the assignment statements.

3.1.4 A Test Program

The following program tests three cases:

1. Four vertices in a line.
2. Four vertices in a ring.
3. Four vertices in a ring with a diagonal.

Testing is limited because of the fixed value of N.

```
procedure put_paths(paths : in path_lengths) is
begin
    for i in 1 .. N sequential loop
        sequential
        put("      ");
        for j in 1 .. N sequential loop
            sequential
            put(paths(i, j));
            put(" ");
        end loop;
        new_line;
    end loop;
end put_paths;

function equal(p, q : path_lengths; i, j : integer) return Boolean is
begin
    if i = N and j = N then
        return p(i, j) = q(i, j);
    elsif i < N and j = N then
        return p(i, j) = q(i, j) and equal(p, q, i + 1, 1);
    elsif i <= N and j < N then
        return p(i, j) = q(i, j) and equal(p, q, i, j + 1);
    end if;
end equal;

function equal_paths(p, q : path_lengths) return Boolean is
begin
    return equal(p, q, 1, 1);
end equal_paths;
```

```
procedure test(message : in string; edges, expected : in path_lengths) is
    paths : path_lengths;
begin
    sequential
    put(message); new_line;
    put("Edge lengths:"); new_line;
    put_paths(edges);
    put("Shortest paths:"); new_line;
    paths := shortest_paths(edges);
    put_paths(paths);
    if equal_paths(paths, expected) then
        put("Succeeded");
    else
        put(">>>> FAILED <<<<");
    end if;
    new_line; new_line;
end test;

procedure main is
begin
    sequential
    put("Testing All-Points Shortest-Path Problem"); new_line;
    put("————————————————————————————————"); new_line;
    new_line;

    test("Four vertices in a line:",
        path_lengths'((0,    1,    1000, 1000),
                      (1,    0,    1,    1000),
                      (1000, 1,    0,    1    ),
                      (1000, 1000, 1,    0    )),
        path_lengths'((0, 1, 2, 3),
                      (1, 0, 1, 2),
                      (2, 1, 0, 1),
                      (3, 2, 1, 0)));

    test("Four vertices in a ring:",
        path_lengths'((0,    1,    8,    1000),
                      (1,    0,    1000, 2    ),
                      (8,    1000, 0,    4    ),
                      (1000, 2,    4,    0    )),
        path_lengths'((0, 1, 7, 3),
                      (1, 0, 6, 2),
                      (7, 6, 0, 4),
                      (3, 2, 4, 0)));
```

```
    test("Four vertices in a ring with a diagonal:",
        path_lengths'((0,    1,    8,    4    ),
                      (1,    0,    1000, 2    ),
                      (8,    1000, 0,    4    ),
                      (4,    2,    4,    0    )),
        path_lengths'((0, 1, 7, 3),
                      (1, 0, 6, 2),
                      (7, 6, 0, 4),
                      (3, 2, 4, 0)));

    put("FINISHED."); new_line;
end main;
```

3.1.5 Test Output

```

3.2 Dirichlet's Problem

3.2.1 Problem Specification

Dirichlet's problem concerns a two-dimensional grid of cells, each having a numeric value. Cells on the boundary of the grid have constant values over time. Internal cells have values that change over time, beginning with initial values at time t = 0. The value of an internal cell at time t+1 is a weighted average of the values of the cell and its immediate neighbors at time t, given by:

$$cell_{i,j}^{t+1} = (4 \times cell_{i,j}^{t} + cell_{i-1,j}^{t} + cell_{i+1,j}^{t} + cell_{i,j-1}^{t} + cell_{i,j+1}^{t})/8.$$

As time progresses, the values of the cells converge to some steady state.

A function is required that satisfies the following specification:

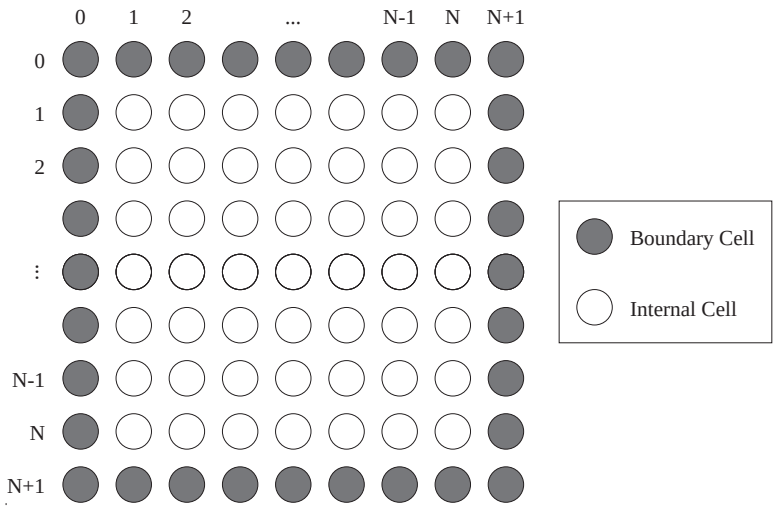

Figure 1: Grid of cells for Dirichlet's problem.

```
type grid is array(0 .. N + 1, 0 .. N + 1) of float;

function dirichlet(input_grid : grid; iterations : integer) return grid;
-- Input Condition:
--    N ≥ 1, and iterations ≥ 0, and
--    input_grid(0, 0) = 0, and input_grid(0, N+1) = 0, and
--    input_grid(N+1, 0) = 0, and input_grid(N+1, N+1) = 0, and
--    input_grid(0, 1..N) = the constant top boundary of a grid, and
--    input_grid(N+1, 1..N) = the constant bottom boundary of a grid, and
--    input_grid(1..N, 0) = the constant left boundary of a grid, and
--    input_grid(1..N, N+1) = the constant right boundary of a grid, and
--    input_grid(1..N, 1..N) = the values of the internal cells of a grid at time t = 0.
-- Output Condition:
--    dirichlet(input_grid, iterations)(0, 0..N+1) = input_grid(0, 0..N+1), and
--    dirichlet(input_grid, iterations)(N+1, 0..N+1) = input_grid(N+1, 0..N+1), and
--    dirichlet(input_grid, iterations)(0..N+1, 0) = input_grid(0..N+1, 0), and
--    dirichlet(input_grid, iterations)(0..N+1, N+1) = input_grid(0..N+1, N+1), and
--    dirichlet(input_grid, iterations)(1..N, 1..N) =
--        the values of the internal cells of the grid at time t = iterations.
```

3.2.2 The Program

```
N : constant integer := 4;

type grid is array(0 .. N + 1, 0 .. N + 1) of float;

function dirichlet(input_grid : grid; iterations : integer) return grid is
    new_grid : grid;
begin
    if iterations = 0 then
        return input_grid;
    else
        for i in 0 .. N + 1 loop
            for j in 0 .. N + 1 loop
                if i = 0 or i = N + 1 or j = 0 or j = N + 1 then
                    new_grid(i, j) := input_grid(i, j);
                else
                    new_grid(i, j) := (4.0 * input_grid(i, j) +
                        input_grid(i - 1, j) + input_grid(i + 1, j) +
                        input_grid(i, j - 1) + input_grid(i, j + 1)    ) / 8.0;
                end if;
            end loop;
        end loop;
        return dirichlet(new_grid, iterations - 1);
    end if;
end dirichlet;
```

3.2.3 Discussion

This program to solve Dirichet's problem demonstrates parallel execution derived from parallel loops and functional composition. Recursion creates a succession of intermediate grids, without the explicit declaration of an array of grids.

If the number of iterations required is zero, the dirichlet function returns the input_grid. Otherwise, the new_grid is defined to be the input_grid after one iteration, and the dirichlet function returns the result of one fewer iterations recursively applied to the new_grid. The recursion terminates (if the number of iterations required is non-negative), because each recursive call requires one fewer iterations.

The N+2 iterations of each loop statement are executed in parallel. Therefore, each level of a dirichlet call consists of $(N+2)^2$ independent paral-

lel assignment statement processes, each defining the value of a different new_grid(i, j).

The recursive dirichlet call is executed in parallel with the calling process. Therefore, the complete executing program consists of a pipeline of parallel dirichlet processes. However, the dependence of the value of new_grid(i, j) on the values of the surrounding components of the input_grid restricts the order and overlapping of the execution of assignment statements between different levels of recursion.

3.2.4 A Test Program

The following program tests three cases:

1. All boundary cells have zero value and all internal cells have the same positive initial value.
2. Top boundary cells have the same positive value, bottom boundary cells have zero value, side boundary cells have values varying smoothly from top to bottom, and all internal cells have zero initial value.
3. Boundary cells have values varying smoothly from a positive value at one corner down to zero at the opposite corner, and all internal cells have zero initial value.

In each case, 100 iterations are performed. The internal cell values are expected to reach a steady state consistent with the boundary cell values.

```
procedure put_grid(g : in grid) is
begin
    for i in 0 .. N + 1 sequential loop
        sequential
        put("      ");
        for j in 0 .. n + 1 sequential loop
            sequential
            put(g(i, j));
            put(" ");
        end loop;
        new_line;
    end loop;
end put_grid;

procedure test(initial_grid : in grid; num_iterations : in integer) is
begin
    sequential
    put("Initial grid:"); new_line;
    put_grid(initial_grid);
    put("After "); put(num_iterations); put(" iterations:"); new_line;
    put_grid(dirichlet(initial_grid, num_iterations));
    new_line;
end test;

procedure main is
begin
    sequential
    put("Testing Dirichlet's Problem"); new_line;
    put("————————————————————"); new_line;
    new_line;

    test(grid'((0.0, 0.0, 0.0, 0.0, 0.0, 0.0),
               (0.0, 9.0, 9.0, 9.0, 9.0, 0.0),
               (0.0, 9.0, 9.0, 9.0, 9.0, 0.0),
               (0.0, 9.0, 9.0, 9.0, 9.0, 0.0),
               (0.0, 9.0, 9.0, 9.0, 9.0, 0.0),
               (0.0, 0.0, 0.0, 0.0, 0.0, 0.0)),
         100);
```

```
    test(grid'((0.0, 5.0, 5.0, 5.0, 5.0, 0.0),

4 Streams and Processes

In the previously presented programs, there is no feedback between the production and consumption of data, and statements are ordered so that production precedes consumption. Therefore, with the addition of appropriate packaging, these Declarative Ada programs are also valid sequential Ada programs. In such programs, parallel execution is possible but not necessary.

However, we can write Declarative Ada programs that involve networks of

parallel processes in which there is feedback in the flow of data between producing and consuming processes. In this section we present two such programs: Hamming's problem and a solution to Dirichlet's problem that explicitly creates a process for every cell in the grid. Neither of these programs can have their statements reordered to make them correct sequential Ada programs. For both programs, parallel execution is necessary.

Communication within networks of parallel processes is often by means of shared lists. Synchronization occurs automatically through processes suspending when they access undefined elements. Lists used for communication between parallel processes are often called streams.

4.1 Hamming's Problem

4.1.1 Problem Specification

A function is required that satisfies the following specification:

```
type node;
type list   is access node;
type node is record
                head : integer;
                tail   : list;
            end record;

function hamming(n : integer) return list;
-- Input Condition:
--    n ≥ 0.
-- Output Condition:
--    hamming(n) = a list, in ascending order, of the first n integers of the
--                 form 2^i × 3^j × 5^k, for all integers i ≥ 0, j ≥ 0, k ≥ 0.
```

4.1.2 The Program

```
type node;
type list   is access node;
type node is record
                head : integer;
                tail   : list;
            end record;
```

```
function multiply(m : integer; numbers : list) return list is
begin
    if numbers = null then
        return null;
    else
        return new node'(m * numbers.head, multiply(m, numbers.tail));
    end if;
end multiply;

function merge(input1, input2 : list) return list is
begin
    if input1 = null then
        return input2;
    elsif input2 = null then
        return input1;
    elsif input1.head < input2.head then
        return new node'(input1.head, merge(input1.tail, input2));
    elsif input2.head < input1.head then
        return new node'(input2.head, merge(input1, input2.tail));
    elsif input1.head = input2.head then
        return new node'(input1.head, merge(input1.tail, input2.tail));
    end if;
end merge;

function truncate(n : integer; numbers : list) return list is
begin
    if n = 0 or numbers = null then
        return null;
    else
        return new node'(numbers.head, truncate(n - 1, numbers.tail));
    end if;
end truncate;

function hamming(n : integer) return list is
    times_2, times_3, times_5, merged, result : list;
begin
    times_2 := multiply(2, result);
    times_3 := multiply(3, result);
    times_5 := multiply(5, result);
    merged := merge(times_2, merge(times_3, times_5));
    result := truncate(n, new node'(1, merged));
    return result;
end hamming;
```

4.1.3 Discussion

The program to solve Hamming's problem demonstrates a network of processes executing in parallel, with feedback in the communication between processes. Lists are used as communication streams.

The hamming function returns the result of the network of parallel processes in Figure 2. The derivation and proof of this solution are explained in [2, Chapter 5]. We do not attempt to repeat this explanation.

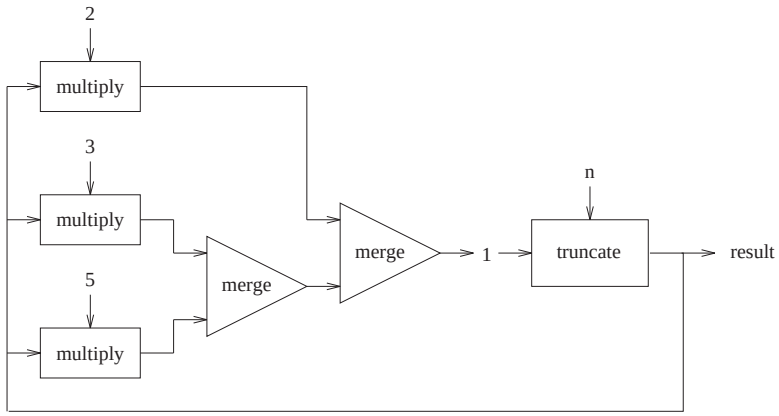

Figure 2: Process network for Hamming's problem.

In the preceding program, the parallel processes are initiated through parallel composition of statements. This allows the communication streams to be given names. An alternative is the following program, where the parallel processes are initiated through functional composition:

```
function hamming(n : integer) return list is
    result : list;
begin
    result := truncate(n, new node'(1, merge(multiply(2, result),
                        merge(multiply(3, result), multiply(5, result)))));
    return result;
end hamming;
```

The choice between composition of statements and functional composition is a subjective matter of preferred style.

4.1.4 A Test Program

The following program tests hamming(0), hamming(1), and hamming(20).

```
function build_list(size : integer;
    i1,  i2,  i3,  i4,  i5,  i6,  i7,  i8,  i9,  i10,
    i11, i12, i13, i14, i15, i16, i17, i18, i19, i20 : integer ) return list is
begin
    if size = 0 then
        return null;
    else
        return new node'(i1, build_list(size - 1,
                                 i2,  i3,  i4,  i5,  i6,  i7,  i8,  i9,  i10, i11,
                                 i12, i13, i14, i15, i16, i17, i18, i19, i20, 0));
    end if;
end build_list;

procedure put_items(items : in list) is
begin
    sequential
    put(items.head);
    if items.tail /= null then
        sequential
        put(" ");
        put_items(items.tail);
    end if;
end put_items;

procedure put_list(items : in list) is
begin
    if items = null then
        put("empty");
    else
        put_items(items);
    end if;
end put_list;
```

```
function equal_lists(list_1, list_2 : list) return Boolean is
begin
    if list_1 = null and list_2 = null then
        return true;
    elsif (list_1 = null and list_2 /= null) or
          (list_2 = null and list_1 /= null) then
        return false;
    else
        return list_1.head = list_2.head and then
                equal_lists(list_1.tail, list_2.tail);
    end if;
end equal_lists;

procedure test(n : in integer; expected : in list) is
    numbers : list;
begin
    sequential
    numbers := hamming(n);
    put("hamming("); put(n); put(") = "); put_list(numbers); new_line;
    if equal_lists(numbers, expected) then
        put("Succeeded");
    else
        put(">>>> FAILED <<<<");
    end if;
    new_line; new_line;
end test;

procedure main is
begin
    sequential
    put("Testing Hamming's Problem"); new_line;
    put("————————————————————"); new_line;
    new_line;
    test(0, null);
    test(1, new node'(1, null));
    test(20, build_list(20, 1,  2,  3,  4,  5,  6,  8,  9,  10, 12,
                        15, 16, 18, 20, 24, 25, 27, 30, 32, 36));
    put("FINISHED."); new_line;
end main;
```

4.1.5 Test Output

```
Testing Hamming's Problem
-------------------------

hamming(0) = empty
Succeeded

Succeeded

FINISHED.
```

4.2 Dirichlet's Problem Revisited

4.2.1 Problem Specification

In this section we present another program that solves Dirichlet's problem, as specified in Section 3.2.1.

4.2.2 The Program

```
N : constant integer := 4;

type grid     is array(0 .. N + 1, 0 .. N + 1) of float;

type node;
type stream   is access node;
type node     is record
                    value : float;
                    more : stream;
                end record;
type streams is array(0 .. N + 1, 0 .. N + 1) of stream;
```

```
procedure boundary_cell(
    iterations  : in  integer;
    fixed_value : in  float;
    to_internal : out stream
) is
    more_to_internal : stream;
begin
    if iterations = 0 then
        to_internal := null;
    else
        to_internal := new node'(fixed_value, more_to_internal);
        boundary_cell(in iterations - 1, in fixed_value, out more_to_internal);
    end if;
end boundary_cell;

procedure internal_cell(
    iterations    : in  integer;
    initial_value : in  float;
    result_value  : out float;
    from_left, from_right, from_above, from_below : in  stream;
    to_left,   to_right,   to_above,   to_below   : out stream
) is
    new_value : float;
    more_to_left, more_to_right, more_to_above, more_to_below : stream;
begin
    if iterations = 0 then
        result_value := initial_value;
        to_left := null; to_right := null; to_above := null; to_below := null;
    else
        to_left  := new node'(initial_value, more_to_left);
        to_right := new node'(initial_value, more_to_right);
        to_above := new node'(initial_value, more_to_above);
        to_below := new node'(initial_value, more_to_below);
        new_value := (4.0 * initial_value +
                      from_left.value + from_right.value +
                      from_above.value + from_below.value) / 8.0;
        internal_cell(in iterations - 1, in new_value, out result_value,
            in from_left.more, in from_right.more,
            in from_above.more, in from_below.more,
            out more_to_left, out more_to_right,
            out more_to_above, out more_to_below);
        end if;
end internal_cell;
```

```
function dirichlet(input_grid : grid; iterations : integer) return grid is
    result : grid;
    to_left, to_right, to_above, to_below : streams;
begin
    for i in 1 .. N loop
        boundary_cell(in iterations, in input_grid(0, i), out to_below(0, i));
        boundary_cell(in iterations, in input_grid(N + 1, i), out to_above(N + 1, i));
        boundary_cell(in iterations, in input_grid(i, 0), out to_right(i, 0));
        boundary_cell(in iterations, in input_grid(i, N + 1), out to_left(i, N + 1));
    end loop;
    for i in 0 .. N + 1 loop
        for j in 0 .. N + 1 loop
            if i = 0 or i = N + 1 or j = 0 or j = N + 1 then
                result(i, j) := input_grid(i, j);
            else
                internal_cell(in iterations, in input_grid(i, j), out result(i, j),
                    in to_right(i, j − 1), in to_left(i, j + 1),
                    in to_below(i − 1, j), in to_above(i + 1, j),
                    out to_left(i, j), out to_right(i, j),
                    out to_above(i, j), out to_below(i, j));
            end if;
        end loop;
    end loop;
    return result;
end dirichlet;
```

4.2.3 Discussion

This program to solve Dirichlet's problem demonstrates a grid of processes executing in parallel, with two-way communication between neighboring cells. Lists are used as communication streams. Parallel loops and arrays of streams are used to create the grid of processes.

The dirichlet function returns a result grid consisting of the input_grid values for the boundary cells and the results of a grid of internal_cell processes for the internal cells.

There is one internal_cell process for each internal cell in the problem and one boundary_cell process for each boundary cell in the problem. Internal_cell processes communicate values to and from their top, bottom, left, and right neighboring processes. Boundary_cell processes communicate values to their

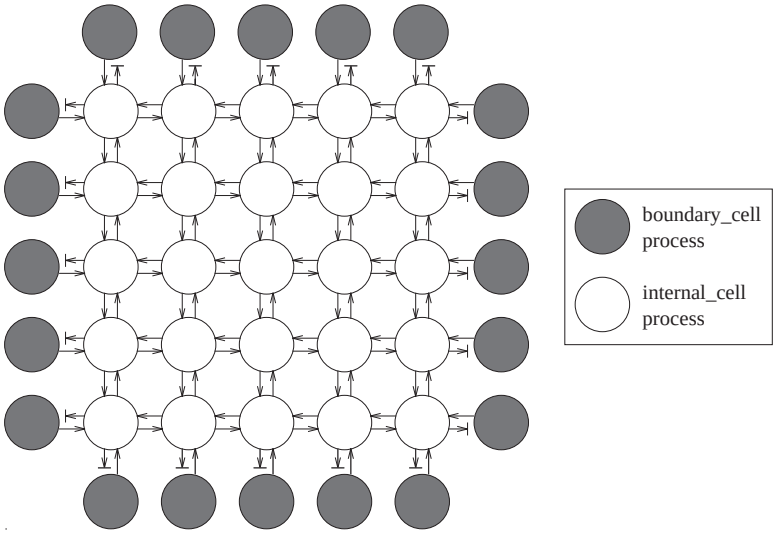

Figure 3: Process grid for Dirichlet's problem.

neighboring internal_cell processes.

The parallel processes are initiated through parallel loops. One loop initiates the boundary_cell processes. Nested loops initiate the internal_cell processes. Two-dimensional arrays of streams provide a means of addressing the shared communication streams during process initiation.

4.2.4 Testing

The program is tested using the same program as in Section 3.2.4. Exactly the same output is produced as in Section 3.2.5.

5 Dining Philosophers

Declarative Ada programs are deterministic: the execution of a program with the same input values will always perform the same computations and assign the same intermediate and output values. If a program executes to

termination, it will always execute to termination. If a program suspends without termination, it will always suspend without termination. If a program terminates with an execution error, it will always terminate with an execution error. Such repeatability is generally considered to be desirable, particularly in program development, testing, and debugging.

However, some problems require a nondeterministic program that interacts with an inherently nondeterministic environment. Since Declarative Ada has no nondeterministic features we propose the use of a *fair merge* procedure from outside of the pure language. The fair merge procedure is described in [7, Section 5] and [3, Chapter 14].

In this section we present a distributed solution to the dining philosophers problem. The environment is a collection of independent processes that each repeatedly request and relinquish access to a shared resource. A control program grants access to the resource, subject to restrictions on which processes can have access simultaneously. Nondeterminism is necessary in the program, to provide fair and efficient access amongst the competing processes.

The specification of the dining philosophers problem and the method of solution that we implement are discussed in [2, Chapter 12], using the nondeterministic UNITY language. However, in our solution, nondeterminism is isolated in the use of the fair merge procedure. All other components of our solution are deterministic.

5.1 Problem Specification

5.1.1 General Specification

This version of the dining philosophers problem concerns a static network of processes, where the processes correspond to the vertices of a finite, undirected, connected graph. The processes are traditionally called philosophers. Each philosopher is in one of three states: thinking, hungry, or eating. The only transitions are from thinking to hungry, hungry to eating, and eating to thinking.

Each philosopher controls its own transitions from thinking to hungry and from eating to thinking. These transitions must satisfy the following re-

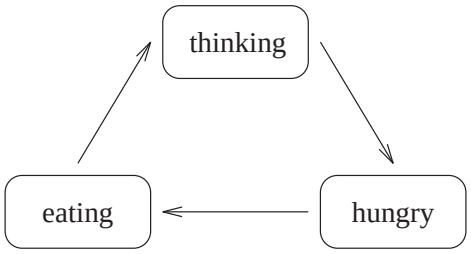

Figure 4: Philosopher state transitions.

quirement:

1. A philosopher must not eat forever, i.e., a philosopher in the eating state must eventually choose to undergo the transition from eating to thinking.

An operating system controls the transitions from hungry to eating. These transitions must satisfy the following requirements:

2. Philosophers that are neighbors (i.e., directly connected in the underlying graph) cannot be in the eating state simultaneously.
3. A philosopher must not remain hungry forever, i.e., a philosopher in the hungry state must eventually be permitted to undergo the transition from hungry to eating.

For instance, with the graph in Figure 5, philosophers 2 and 3 can be in the eating state simultaneously, but no other philosopher can be in the eating state simultaneously with either of philosophers 1 or 4.

A solution to the dining philosophers problem is an operating system that satisfies requirements 2 and 3 if all philosophers satisfy requirement 1.

5.1.2 Specification of a Distributed System

We require a distributed solution to the dining philosophers problem. A centralized operating system controlling the hungry to eating transitions of

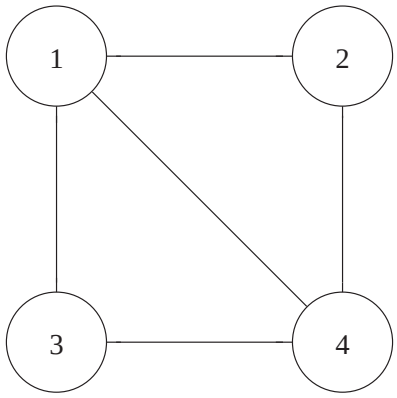

Figure 5: Example of a graph for the dining philosophers problem.

all processes could be a bottleneck in execution, particularly if the network is large and physically distributed, and transitions are frequent. Instead, we split each philosopher into two components: a user process that we call the client, and an operating system process that we call the server.

Client processes control the thinking to hungry and eating to thinking transitions. Server processes control the hungry to eating transitions. Each client process communicates only with its server process. Each server process communicates with its client process and also with neighboring server processes.

The server processes are identical processes that cooperate to provide distributed control of the hungry to eating transitions of all the philosophers. The client processes each represent only one philosopher, and can be different from one another.

As a solution to the dining philosophers problem we require:

- A defined interface between server processes,
- A defined interface between server and client processes, and
- An implementation of server processes,

such that a network of server and client processes can be created that will

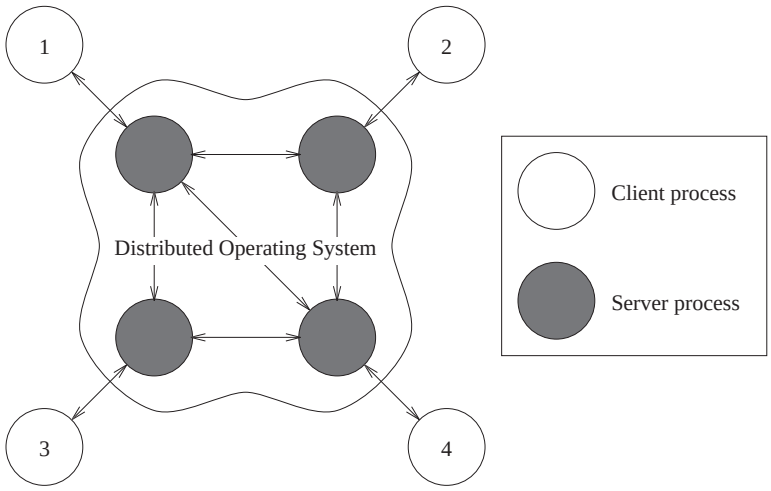

Figure 6: Distributed system for the graph in Figure 5.

satisfy the specification of the problem.

One solution is presented in the following sections. The derivation and proof of this solution are explained in [2, Chapter 12]. We do not attempt to repeat this explanation.

5.2 The Interface Between Server and Client Processes

The server and client processes have interfaces of the following form:

```
type message is record
                    sender : integer;
                    kind   : (thinking, hungry, eating, fork, request);
                end record;

type node;
type stream  is access node;
type node    is record
                    item : message;
                    more : stream;
                end record;

procedure server(
    state    : in  (thinking, hungry, eating);
    N        : in  integer;
    ids      : in  array(1 .. N) of integer;
    forks    : in  array(1 .. N) of (clean, dirty, not_held);
    requests : in  array(1 .. N) of Boolean;
    input    : in  stream;
    output   : out array(0 .. N) of stream
);

procedure client(
    from_server : in  stream;
    to_server   : out stream
);
```

The meaning of the parameters of a server process are as follows:

1. state : **in** (thinking, hungry, eating).

   The state of the client.

2. N : **in** integer.

   Neighboring servers are numbered #1 to #N.

3. ids : **in array**(1 .. N) **of** integer.

   Neighboring server #i considers this server to be its neighboring server #ids(i).

4. forks : **in array**(1 .. N) **of** (clean, dirty, not_held).

   forks(i) is the state of the fork shared with neighboring server #i.

5. requests : **in array**(1 .. N) **of** Boolean.

   requests(i) indicates whether or not the request shared with neighboring server #i is held by this server.

6. input: **in** stream.

   The fair merge of streams of messages from the client and neighboring servers. Messages from the client have sender = 0 and kind $\in$ {thinking, hungry}, and messages from neighboring server #i have sender = i and kind $\in$ {fork, request}.

7. output : **out array**(0 .. N) **of** stream.

   output(0) is a stream of messages to the client, and output(1 .. N) are streams of messages to neighboring servers #1 to #N. Messages to the client have sender = 0 and kind = eating, and messages to neighboring server #i have sender = ids(i) and kind $\in$ {fork, request}.

There is no global numbering scheme amongst the servers. Different servers can have different numbers of neighboring servers, and each server numbers its neighbors locally. The amount of storage required by each server and the efficiency of its operations depend only on the number of neighboring servers, not on the total number of servers in the system.

Messages between a client and server are as follows:

1. A hungry message from the client to the server indicates that the client has made the transition from thinking to hungry.
2. An eating message from the server to the client indicates that the client can make the transition from hungry to eating.
3. A thinking message from the client to the server indicates that the client has made the transition from eating to thinking.

Messages between neighboring servers are either forks or requests (for forks). Exactly one fork and one request are shared between every pair of neighboring servers. Priorities between pairs of neighboring servers are maintained using the forks, which can be either clean or dirty. A server does not send an eating message to its client unless the server holds the forks for all its neighboring servers.

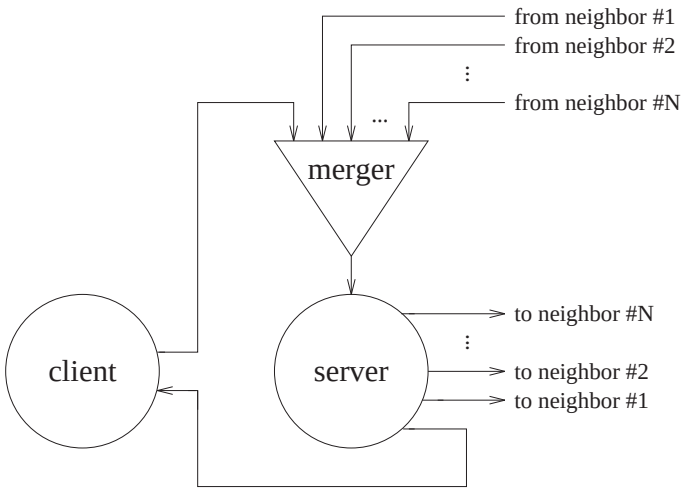

Figure 7: Communication between servers and clients.

Initially we require:

1. All clients and servers are in the thinking state.
2. The fork shared between each pair of servers is held by one of the servers, and the corresponding request is held by the other one of the servers.
3. All forks are dirty.
4. The priority graph (with each edge directed toward the server that holds the fork for that edge) is acyclic.

5.3 The Server Program

```
-- Maximum Number Of Neighbors

max_neighbors : constant integer := 3;

-- Message Kinds

thinking : constant integer := 0;
hungry   : constant integer := 1;
eating   : constant integer := 2;
fork     : constant integer := 3;
request  : constant integer := 4;

-- Fork States

clean     : constant integer := 0;
dirty     : constant integer := 1;
not_held  : constant integer := 2;

-- Sender Identification Numbers In Messages To Neighbors

type id_array is array(1 .. max_neighbors) of integer;

-- Streams Of Messages

type message is record
                    sender : integer;
                    kind   : integer;
                end record;

type node;
type stream  is access node;
type node    is record
                    item : message;
                    more: stream;
                end record;

type streams is array(0 .. max_neighbors) of stream;

-- Fork and Request Status Arrays

type fork_array    is array(1 .. max_neighbors) of integer;
type request_array is array(1 .. max_neighbors) of Boolean;
```

```
-- Send A Message

procedure send(output       : out streams;
               more_output : in  streams;
               N            : in  integer;
               destination  : in  integer;
               sender       : in  integer;
               kind         : in  integer  ) is
begin
    for i in 0 .. N loop
        if i /= destination then
            output(i) := more_output(i);
        else
            output(i) := new node'(message'(sender, kind), more_output(i));
        end if;
    end loop;
end send;

-- Fork Status Array Containing All Dirty Forks

function dirty_forks(N : integer) return fork_array is
    forks : fork_array;
begin
    for i in 1 .. N loop
        forks(i) := dirty;
    end loop;
    return forks;
end dirty_forks;

-- Are All The Forks Held?

function holds_all(N : integer; forks : fork_array) return Boolean is
begin
    if N = 0 then
        return true;
    elsif forks(N) = not_held then
        return false;
    else
        return holds_all(N - 1, forks);
    end if;
end holds_all;
```

```
-- Update Fork Status Array

function update_forks(N          : integer;
                      forks      : fork_array;
                      id         : integer;
                      fork_state : integer     ) return fork_array is
   updated_forks : fork_array;
begin
   for i in 1 .. N loop
      if i = id then
         updated_forks(i) := fork_state;
      else
         updated_forks(i) := forks(i);
      end if;
   end loop;
   return updated_forks;
end update_forks;

-- Update Request Status Array

function update_requests(N             : integer;
                         requests      : request_array;
                         id            : integer;
                         request_state : Boolean       ) return request_array is
   updated_requests : request_array;
begin
   for i in 1 .. N loop
      if i = id then
         updated_requests(i) := request_state;
      else
         updated_requests(i) := requests(i);
      end if;
   end loop;
   return updated_requests;
end update_requests;
```

```
-- Send Forks To All Neighbors Wanting The Fork

procedure send_forks(output          : out streams;
                     more_output     : in  streams;
                     N               : in  integer;
                     ids             : in  id_array;

5.4 Discussion of the Server Program

A server process suspends until an input message is defined. Then, depending on the server state, the kind of the message, and the forks and requests held by the server, one of nine possible cases is deterministically chosen to be executed:

1. State is thinking, a hungry message is received from the client, and all the forks are held.
2. State is thinking, a hungry message is received from the client, and all the forks are not held.
3. State is thinking and a request is received from a neighboring server.
4. State is hungry, a fork is received from a neighboring server, and all the forks are now held.
5. State is hungry, a fork is received from a neighboring server, and all the forks are not yet held.
6. State is hungry, a request is received from a neighboring server, and the fork shared with that neighbor is clean.
7. State is hungry, a request is received from a neighboring server, and the fork shared with that neighbor is dirty.
8. State is eating and a thinking message is received from the client.
9. State is eating and a request is received from a neighboring server.

In each case, appropriate messages are sent in response, and the server recurses with appropriately modified state, forks, requests, and streams, to await the next input message. Examination shows that each case maintains the invariants stated in the header of the server program.

If the language provided a nondeterministic choice construct, we could write an equivalent program with fewer cases. For example, the four cases in which a request is received could be combined. However, such a program would maintain weaker invariants on the server. Therefore, an argument can be made that the program would be more difficult to reason about.

5.5 A Test Program

The following test program creates the configuration of four philosophers in Figure 5 and Figure 6. The clients eat and think for an amount of time determined by a busy wait. Each client completes five thinking-hungry-eating cycles, then terminates in the thinking state. The clients send messages to a single printer process that outputs a trace of the client state-transitions. The global numbering of philosophers is only used in producing the output. The initial distribution of forks and requests gives an acyclic priority graph.

The merger procedure used in the test program cannot be written in Declarative Ada. To execute the program, a merger procedure was imported from PCN [3, 5].

```
procedure think(time : in integer) is
begin
    if time > 0 then
        think(in time - 1);
    end if;
end think;

procedure eat(time : in integer) is
begin
    if time > 0 then
        eat(in time - 1);
    end if;
end eat;
```

```
procedure client(
    id          : in  integer;
    count       : in  integer;
    from_server : in  stream;
    to_server   : out stream;
    to_printer  : out stream
) is
    eating_message : message;
begin
    sequential
    to_printer := new node;
    to_printer.item := message'(id, thinking);
    if count > 0 then
        sequential
        think(10);
        to_server := new node;
        to_server.item := message'(0, hungry);
        to_printer.more := new node;
        to_printer.more.item := message'(id, hungry);
        eating_message := from_server.item;
        to_printer.more.more := new node;
        to_printer.more.more.item := message'(id, eating);
        eat(10);
        to_server.more := new node;
        to_server.more.item := message'(0, thinking);
        client(in id, in count - 1, in from_server.more,
            out to_server.more.more, out to_printer.more.more.more);
    end if;
end client;
```

```
procedure printer(messages : in stream) is
begin
    if messages /= null then
        sequential
        put("Philosopher ");
        put(messages.item.sender);
        if messages.item.kind = thinking then
            put(" starts thinking");
        elsif messages.item.kind = hungry then
            put(" becomes hungry");
        elsif messages.item.kind = eating then
            put(" starts eating");
        end if;
        new_line;
        printer(in messages.more);
    end if;
end printer;

procedure merger(input_1, ... , input_n : in stream; output : out stream);
-- Fair-merge procedure imported from outside of the language.

procedure main is
    client1_out,  client2_out,  client3_out,  client4_out  : stream;
    client1_print, client2_print, client3_print, client4_print : stream;

    merger(in client4_out, in server1_out(3), in server2_out(2), in server3_out(2),
        out server4_in);
end main;
```

5.6 Test Output

Examination of the test output shows that each philosopher completes exactly five thinking-hungry-eating cycles. As we require, no philosopher eats simultaneously with either of philosophers 1 or 4, but as is permitted, philosophers 2 and 3 do eat simultaneously.

```
Philosopher 1 starts thinking
Philosopher 2 starts thinking
Philosopher 3 starts thinking
Philosopher 4 starts thinking
Philosopher 1 becomes hungry
Philosopher 2 becomes hungry
Philosopher 3 becomes hungry
Philosopher 4 becomes hungry
Philosopher 1 starts eating
Philosopher 1 starts thinking
Philosopher 1 becomes hungry
Philosopher 4 starts eating
```

```
Philosopher 4 starts thinking
Philosopher 4 becomes hungry
Philosopher 2 starts eating
Philosopher 3 starts eating
Philosopher 2 starts thinking
Philosopher 3 starts thinking
Philosopher 2 becomes hungry
Philosopher 3 becomes hungry
Philosopher 1 starts eating
Philosopher 1 starts thinking
Philosopher 1 becomes hungry
Philosopher 4 starts eating
Philosopher 4 starts thinking
Philosopher 4 becomes hungry
Philosopher 2 starts eating
Philosopher 3 starts eating
Philosopher 2 starts thinking
Philosopher 3 starts thinking
Philosopher 2 becomes hungry
Philosopher 3 becomes hungry
Philosopher 1 starts eating
Philosopher 1 starts thinking
Philosopher 1 becomes hungry
Philosopher 4 starts eating
Philosopher 4 starts thinking
Philosopher 4 becomes hungry
Philosopher 2 starts eating
Philosopher 3 starts eating
Philosopher 2 starts thinking
Philosopher 3 starts thinking
Philosopher 2 becomes hungry
Philosopher 3 becomes hungry
Philosopher 1 starts eating
Philosopher 1 starts thinking
Philosopher 1 becomes hungry
Philosopher 4 starts eating
Philosopher 4 starts thinking
Philosopher 4 becomes hungry
Philosopher 2 starts eating
Philosopher 3 starts eating
Philosopher 2 starts thinking
Philosopher 3 starts thinking
Philosopher 2 becomes hungry
Philosopher 3 becomes hungry
Philosopher 1 starts eating
Philosopher 1 starts thinking
Philosopher 4 starts eating
```

```
Philosopher 4 starts thinking
Philosopher 2 starts eating
Philosopher 3 starts eating
Philosopher 2 starts thinking
Philosopher 3 starts thinking
```
